ABSTRACT

Aim To study the combined effects of climate change on connectivity between marine protected areas (MPAs) and larval supply to the continental shelf.

Location The Mediterranean Sea, where sea surface temperatures are expected to strongly increase by the end of the 21st century, represents an archetypal situation with a dense MPA network but resource overexploitation outside.

Methods Using an individual-based mechanistic model of larval transport, forced with an emission-driven regional climate change scenario for the Mediterranean Sea, we explored the combined effects of changes in hydrodynamics, adult reproductive timing and larval dispersal on the connectivity among MPAs and their ability to seed fished areas with larvae.

Results We show that, over the period 1970–2099, larval dispersal distances would decrease by 10%, the continental shelf area seeded with larvae would decrease by 3% and the larval retention fraction would increase by 5%, resulting in higher concentration of larvae in smaller areas of the continental shelf. However, connectance within the MPA network would increase by 5% as more northern MPAs would become suitable for reproduction with increasing temperatures. We also show that the effects of changes in adult reproductive timing and larval dispersal on connectivity patterns are additive.

Main conclusions Climate change will influence connectivity and the effectiveness of MPA networks, and should receive more attention in future conservation planning and large-scale population dynamics.

Keywords
Biophysical model, conservation planning, *Epinephelus marginatus*, larval dispersal, larval growth rate, reproductive timing.

INTRODUCTION

Habitat destruction and fragmentation through human activities threaten species survival mainly because of the isolation of local populations (Vitousek *et al.*, 1997; Sala *et al.*, 2000; Foley *et al.*, 2005). Local isolated populations are often of small size and are at risk of extinction through demographic and genetic stochasticity (Gilpin & Soulé, 1986; Gaggiotti & Hanski, 2004; Frankham, 2005). The isolation of local populations also limits the rescue of already imperilled populations [i.e. rescue effect; (Schiffers *et al.*, 2013)] and the possibilities of (re)colonization for empty habitat patches (Hanski & Gaggiotti, 2004).

Reducing the risk of species extinction requires both limiting habitat loss and avoiding population isolation. Protected areas (PAs) appear as effective tools to protect species from extinction through habitat conservation (Halpern, 2003; Rodrigues *et al.*, 2004). However, to avoid population isolation, PAs must represent a connected ecological network at the landscape or regional scale (Noss & Daly, 2006). Only connected networks allow individual movements among PAs through the matrix of unprotected habitats (Lindenmayer *et al.*, 2008). It is now well recognized that landscape connectivity – dispersal in heterogeneous landscape (Taylor *et al.*, 1993; Kool *et al.*, 2012; Baguette *et al.*, 2013) – is an essential feature for the performance of PA networks.

Landscape connectivity, through the movements of individuals and genes in the landscape, influences population viability, metapopulation persistence and resilience to disturbance (Crooks & Sanjayan, 2006). In the case of exploited species, landscape connectivity also determines the potential benefits of PAs for areas open to harvest. This aspect is widely acknowledged for marine species, for which marine-protected areas (MPAs) can act as a source of adult spillover or larval export for nearby fished areas. For terrestrial species, emigration from PAs allows for recolonization of empty patches and increases yield for game species subject to hunting (Ahlering *et al.*, 2012; Tolon *et al.*, 2012; Di Minin *et al.*, 2013).

The functioning and effectiveness of PA networks will further depend on the effects of global climate change both on species distribution (Edwards & Richardson, 2004; Parmesan, 2006; Bellard *et al.*, 2012) and connectivity. Accounting for climate change effects on connectivity when planning future networks has been neglected so far while it is a crucial aspect of systematic conservation planning (Magris *et al.*, 2014). However, connectivity among PAs will be affected by direct and indirect effects on landscape structure and individual dispersal abilities, acting on the emigration, transfer and immigration phase of dispersal (Travis *et al.*, 2013). For example, the dispersal patterns of wind-dispersed plants will change as a result of changes in wind patterns (Bullock *et al.*, 2012); the initiation of migration in moths is positively dependent on temperature and will shift temporally following temperature increase (Battisti *et al.*, 2006). Moreover, these structural and functional changes can interact in a potentially synergistic, additive or antagonistic way (Doak & Morris, 2010; Lischka & Riebesell, 2012; Brochier *et al.*, 2013). Scenarios are thus urgently needed to disentangle the various effects by considering all processes, mechanisms, predictions and uncertainties.

In this work, we will illustrate the effects of climate change on connectivity for the network of MPAs in the Mediterranean Sea. MPAs have been established around the globe to counteract the ever increasing over-exploitation of resources (Halpern, 2003). MPAs are indisputably valuable management tools as they promote habitat and species conservation, but also provide additional income from fishing through individual spillover and larval dispersal beyond MPA boundaries (Gaines *et al.*, 2010). The effectiveness of MPAs in protecting species and providing fisheries benefits is critically dependent on connectivity (Almany *et al.*, 2009). For most coastal marine species, especially sessile and benthic species, connectivity is achieved thanks to larval dispersal (Galindo *et al.*, 2006; Cowen & Sponaugle, 2009; Kool *et al.*, 2010) and must be high enough to ensure ecological and evolutionary links among MPAs and sufficient larval export towards exploited areas (Hastings & Botsford, 2003; Botsford *et al.*, 2009; Gaines *et al.*, 2010). Up to now, however, few studies have accounted for the impact of climate change on future connectivity patterns (Ayata *et al.*, 2010; Lett *et al.*, 2010), and none has explicitly addressed whether MPA networks will continue to ensure population persistence.

The mechanisms controlling larval dispersal and their response to the changing environmental conditions will dictate how connectivity will change in the future (Munday *et al.*, 2009a; Lett *et al.*, 2010; Brochier *et al.*, 2013). Date of spawning, number of spawned larvae, larval mortality, behaviour, growth but also modifications of the seascape through changes in sea currents and habitat availability will be influenced by such environmental modifications (Munday *et al.*, 2009a). These interacting processes, all sensitive to climate change, are thus likely to influence the geographic extent of larval transport and the final pattern of connectivity, potentially imperilling the ability of MPA networks to sustain exploited populations. Indeed, spawning time is expected to shift with climate warming as a result of increased temperatures and the dependence of spawning behaviour on environmental clues such as temperature (Lett *et al.*, 2010). Larval growth rates can then increase thanks to faster metabolic activity (O'Connor *et al.*, 2007; Munday *et al.*, 2009a), allowing larvae to attain metamorphosis quicker and thus reducing the duration of larval transport and potentially inducing a lower connectivity. Finally, climate change also modifies hydrodynamics, sea-atmosphere exchanges and ultimately the patterns of sea current velocities (direction and speed) (Somot *et al.*, 2006; Durrieu de Madron *et al.*, 2011; Dubois *et al.*, 2012; Brochier *et al.*, 2013), which could alter the dispersal routes of larvae. Here, we investigate how these three processes, namely change in reproductive timing, change in larval growth rates and change in current velocities, are likely to affect, alone or in combination, connectivity patterns among MPAs and larval supply to fished areas under climate change. Moreover, we test whether these aspects would have additive, synergistic or antagonistic effects, that is, whether combined effects are simply predictable from single effects (additive) or whether the effects amplify (synergy) or inhibit (antagonism) each other in a non-additive manner. We use the Mediterranean Sea as an archetypal situation where (1) there is a dense MPA network (Micheli *et al.*, 2013) (Fig. 1a), (2) sea surface temperatures are expected to strongly increase by the end of the 21st century [+2.8 °C for an IPCC-A2 scenario for example in the study of Somot *et al.* (2006)] (Fig. 1b and c), and (3) where many fish species are overexploited with population persistence depending on conservation effort (Coll *et al.*, 2012).

METHODS

Spatial distribution of MPAs

The Mediterranean Sea contains approximately a 100 coastal MPAs of various sizes (Abdulla *et al.*, 2009). MPAs were digitized on the basis of MedPan data (http://www.medpan.org/) as well as from maps, polygons and GPS coordinates provided by managers (Mouillot *et al.*, 2011; Andrello *et al.*, 2013) (Fig. 1a).
Figure 1 The locations of the 99 MPAs and the Mediterranean ecoregions (Spalding *et al.*, 2007) (a) and sea surface temperatures in 1970–1999 (b) and 2070–2099 (c). ALB, Alboran Sea; WEST, Western Mediterranean; TUN, Tunisian Plateau and Gulf of Sidra; ION, Ionian Sea; ADR, Adriatic Sea; AEG, Aegean Sea; LEV, Levantine Sea. The size of blue circles in (a) does not reflect MPA size. Temperatures are averages over daily temperatures in August for the two periods.

Hydrodynamic model and larval dispersal simulation

Three-dimensional sea current velocities were obtained from a transient scenario simulation (1970–2099) following the IPCC-A2 hypothesis and carried out with the Mediterranean regional ocean circulation model NEMOMED8 (Beuvier *et al.*, 2010). The ocean model forcings and the hydrodynamic modelling methodology follow Somot *et al.* (2006).

Daily outputs of zonal and meridional velocities from NEMOMED8 were used to simulate larval dispersion using the software ICHTHYOP 3.2 (Lett *et al.*, 2008). For a single year, we released 10,000 larvae per MPA, providing a lower limit of 0.0001 for connection probability. Larval releases in the centroid of each MPA were spread over summer months (1 July–15 September), according to the spawning rules defined below.

Functional relationships and parameters for larval release, growth, settlement and adult spawning were set following field observations and laboratory study carried out on the dusky grouper (*Epinephelus marginatus* Lowe, 1834), which is sedentary to coastal reefs and territorial in its adult phase (Lembo *et al.*, 1999; Pastor *et al.*, 2009; Afonso *et al.*, 2011). Due to its slow growth and late maturation (Renones *et al.*, 2007, 2010), *E. marginatus* should be considered as a 'conservation-dependent' species, a species for which the role of MPAs is critical for maintaining a viable population (Afonso *et al.*, 2011; Andrello *et al.*, 2013). Observations of spawning in the field showed that a threshold temperature of 23 °C must be attained for spawning behaviour to take place (Hereu *et al.*, 2006). According to larval rearing studies, larvae reach ~20 mm body length in ~30 days at 23 °C constant temperature (Cunha *et al.*, 2009), suggesting a mean daily length increment ~0.66 mm day^{-1}. Larvae become competent to settle between 15 and 20 mm body length (Cunha *et al.*, 2009), so we set settlement length L_S = 15 mm. Larvae were subject to passive transport only without active swimming behaviour. We then tested the sensitivity of model results to settlement length and to larval behaviour (see 'sensitivity analyses' below). Further details on the hydrodynamic model and larval dispersal simulation are given in Appendix S1 in Supporting Information.

Connectivity variables

Four variables produced by our simulation of larval dispersal were used to measure connectivity among MPAs and larval export to fished areas (Andrello *et al.*, 2013):

1. *Larval dispersal distance*: measured as the great-circle distance between the positions of larvae at the end and at the beginning of larval transport. The reported value is the median value over all larvae and MPAs.

2. *Connectance*: the percentage of connections with non-zero probability out of the total number of connections between MPAs. Connectance is a measure of connectivity for the system of MPAs as a whole and is indicative of the ability of the system to act as a true network.

3. *Seeded area*: area of the continental shelf seeded from MPAs, calculated as the percentage of grid cells containing at least 1 larva out of the total number of grid cells. This metric and the following one (retention) are indicative of the ability of MPAs to provide benefits to exploited areas. Specifically, the extent of seeded area measures the spatial balance of the larval export that may benefit fisheries.

4. *Retention*: larval retention on the continental shelf – the percentage of released larvae over the continental shelf at the end of larval transport out of the total number of released

larvae – indicates the magnitude of larval export benefits by taking into account the loss of larvae to unfavourable habitats.

Scenario analyses

Temperature (T) affects the timing of adult spawning and the rate of larval growth. We explored four scenarios including or not these two temperature-dependent processes (baseline, growth, spawning, combined). In the first scenario (baseline), larvae were released every day independently of temperature and their growth rate was independent of temperature (0.66 mm day^{-1}). This scenario gives the expected change in connectivity due to changes in sea current velocities only. In the second scenario (growth), larval releases were independent of temperature, but larval growth was temperature-dependent. For simplicity, we used a linear relationship between larval growth rate and T, even if the real relationship might be more complex (e.g. Gaussian). Larval growth rate was 0.027 T; this value was chosen to recover the daily growth rate (0.66 mm day^{-1}) when T = 23 °C. This scenario reproduces the effects of changes in current velocities and larval growth on connectivity. In the third scenario (spawning), larval releases were temperature-dependent, and larval growth was temperature-independent. Larvae were released when T in the release point was above 23 °C. This resulted in a different number of larval releases per MPA, but the total number of released larvae was kept constant (10,000 per year and MPA). This scenario gives the expected change in connectivity due to changes in current velocities and spawning time. In the fourth scenario (combined), both larval releases and larval growth were temperature-dependent. The fourth scenario reproduces the combined effects of changes in current velocities, larval growth and spawning time on connectivity. Each scenario took approximately 310 days of total computing time, subdivided into parallel runs of 30 minutes each on the CIMENT computing grid infrastructure (https://ciment.ujf-grenoble.fr).

For each scenario, we estimated the relationship between response variables (dispersal distance, connectance, seeded area and retention fraction) and time, and we tested for the additivity of the growth and spawning effects using a linear model

$$y = \beta_0 + \beta_1 t + \beta_2 s + \beta_3 g + \beta_4 sg + \beta_5 ts + \beta_6 tg + \beta_7 tsg + \varepsilon \tag{1}$$

Here, y is the response variable (one of dispersal distance, connectance, seeded area and retention), t is the year and ε is the error term. s and g are dummy variables defining spawning and growth: $s = 0$ for temperature-independent spawning (base and growth scenarios) and $s = 1$ for temperature-dependent spawning (spawning and combined scenarios). Similarly, $g = 0$ for temperature-independent growth (base and spawning scenarios) and $g = 1$ for

temperature-dependent growth (growth and combined scenario). The year t was transformed by subtracting 1970 so that the intercept terms (β_0, β_2, β_3 and β_4) are the predicted response variables at the beginning of the series (year 1970). The intercept coefficient (β_0) is then the predicted value of the response variables in 1970, while the year coefficient (β_1) is the annual increase in the response variables when larval growth and adult spawning are independent on temperature. The growth (β_2) and spawning (β_3) coefficients are the effects of larval growth and adult spawning, respectively, on the explanatory variables in 1970, and the interaction between them indicate whether this effect is additive ($\beta_4 = 0$), compensatory ($\beta_4 < 0$) or synergistic ($\beta_4 > 0$). The interaction between growth and year (β_5) and between spawning and year (β_6) are the effects of larval growth and spawning, respectively, on the annual increase of response variables. The interaction between year, growth and spawning indicates whether these effects are additive ($\beta_7 = 0$), compensatory ($\beta_7 < 0$) or synergistic ($\beta_7 > 0$). We used a stepwise procedure for selecting the optimal model both backward from the full model and forward from the null model on the basis of the Akaike Information Criterion, in R (R Core Team, 2012). The backward and forward procedure always converged to the same model. Ninety-five per cent confidence intervals for regression lines were estimated through the R function *stat_smooth* in package *ggplot2* (Wickham, 2009). See Appendix S1 for further details on statistical analyses and sensitivity analyses.

RESULTS

For dispersal distance, connectance and seeded area, the best model includes year, spawning, and growth as explanatory variables, and the interaction between year and growth and between year and spawning (Table 1). For retention, the best model includes year and growth and the interaction between them. The interaction between growth and spawning (β_4) is always dropped, indicating that the effects of larval growth and adult spawning on connectivity are additive. Similarly, the interaction between growth, spawning and year (β_7) is always dropped, indicating that the effects of larval growth and adult spawning on the annual increase in connectivity are additive: the slope of red lines in Fig. 2 (combined effects of larval growth and adult spawning) is the sum of the slopes of the grey, blue (adult spawning) and green (larval growth) lines. The residuals of all models are normally distributed and have homogenous variances, confirming the appropriateness of the linear relationship for modelling the four response variables.

Dispersal distances are expected to decrease by 4% as a consequence of hydrodynamic changes only. The adult spawning coefficient (β_5) is not significant, indicating that changes in adult spawning timing would not affect this decrease in dispersal distances. The change in larval growth rate would further magnify the decrease in dispersal distances, which would be reduced by 10% by the end of this

Table 1 Fitted linear models for the four connectivity variables

	Intercept β_0	Year β_1	Spawning β_2	Growth β_3	Year*Spawning β_5	Year*Growth β_6	Adj-R^2	p
Dispersal distance	78.202***	−0.026*	−2.583*	12.904***	0.025	−0.067***	0.3811	< 2.2 × 10^{-16}
Connectance	0.02839***	0.00000	−0.00228***	0.00167***	0.00002***	−0.00001***	0.24780	< 2.2 × 10^{-16}
Seeded area	0.73572***	−0.00010**	−0.00795**	0.01593***	0.00007*	−0.00016***	0.1734	< 2.2 × 10^{-16}

*, $0.01 < p < 0.05$; **, $0.001 < p < 0.01$; ***, $p < 0.001$.

Figure 2 Regression of connectivity variables on time in the four simulation scenarios. (a, b, c, d) Dispersal distance; (e, f, g, h) connectance; (i, j, k, l) seeded area; and (m, n, o, p) retention. Solid lines are estimated regressions and shaded areas are 95% confidence intervals.

century (Fig. 2d). Thus, the effect of climate change on larval growth rates would be more important than those on adult spawning timing and hydrodynamics.

By contrast, the temporal changes in connectance are driven by the effects of temperature on adult spawning timing. While hydrodynamics changes do not affect connectance, changes in adult spawning timing increase connectance by 11%. The effects of temperature on larval growth would mitigate this increase, leading to a net 5% increase in connectance due to the combined effects of climate change on hydrodynamics, larval growth and adult spawning timing (Fig. 2h). Maps showing connections between MPAs for present and future periods (Fig. 3) confirm that the general pattern of spatial connectivity would remain unchanged, but long-distance connections are expected to be lost.

The area of continental shelf seeded by MPAs would slightly decrease with climate change. In the absence of effects on adult spawning timing and larval growth, changes in hydrodynamics alone would lead to a 2% reduction in seeded area. The effect of temperature on adult spawning would mitigate this trend and produce < 1% of decrease in seeded area, while the effects of temperature on larval growth would accentuate it, resulting in a 5% decrease. The net effect of all processes would be a 3% decrease in seeded area (Fig. 2l).
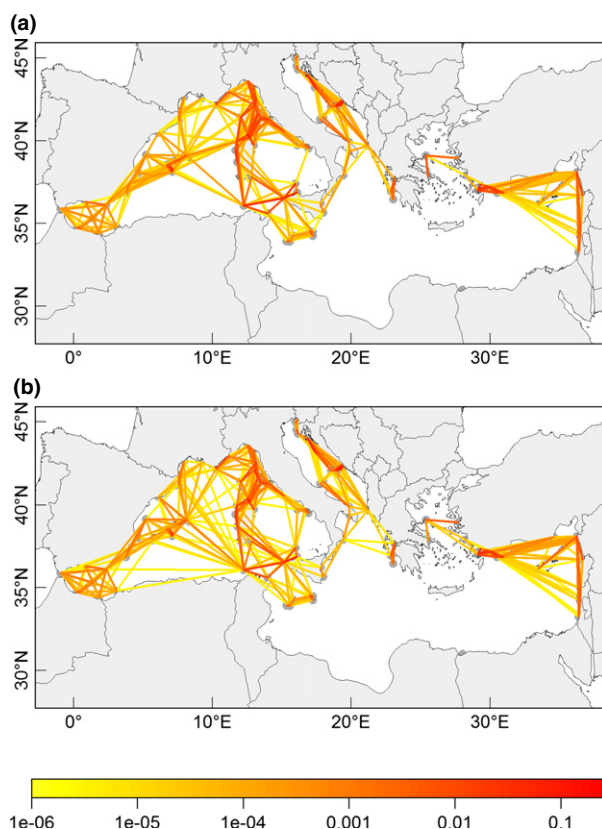

Hydrodynamic changes would not influence the fraction of larvae retained on the continental shelf (larval retention), as the year coefficient (β_1) is not significant. Similarly, changes in adult spawning timing would have no effect on retention, since the spawning variable is dropped from the best model. Conversely, the effects of climate change on larval growth rates would lead to a 5% increase in larval retention (Fig. 2p).

Larval behaviour has no effect on the annual change in dispersal distance, connectance, seeded area or retention: the interaction between larval behaviour and time ($\beta_3 \neq 0$) is always dropped from the model (see Table S1 and Fig. S1 in Supporting Information). The same is true for the threshold body length for larval settlement (see Table S2 and Fig. S2 in Supporting Information).

DISCUSSION

Using an individual-based, mechanistic model of larval transport, forced with an emission-driven regional climate change scenario of the Mediterranean Sea, we have explored the combined effects of changes in hydrodynamics, adult reproductive timing and larval growth rates (both temperature-dependent) on connectivity among MPAs and their ability to seed fished areas with larvae. We have shown that larval dispersal distances would decrease by 10% and connectance of MPAs would increase by 5% over the period 1970–2099. The extent of continental shelf seeded by MPAs would also decrease by 3%, while larval retention on the continental shelf would increase by 5%, resulting in higher concentration of larvae in smaller areas of the continental shelf. Thus, we observed that climate change would affect all metrics of connectivity (larval dispersal distance, connectance, area of the continental shelf seeded with larvae and larval retention fraction on the continental shelf) through various additive mechanisms (changes in hydrodynamics, adult reproductive timing and larval growth rates).

Impact of climate change on different metrics of connectivity

The importance of these mechanisms in response to climate change scenarios depend on which metric of connectivity is considered. While larval dispersal distances would decrease, the connectance of the system of MPAs would be strengthened; the extent of the continental shelf seeded by MPAs would decrease, but the concentration of larvae in the seeded areas would increase.

A decrease in larval dispersal distances would decrease gene flow and strengthen population structure, possibly leading to a more modular and fragmented system (Watson *et al.*, 2011). At the opposite, increased connectance among MPAs would ensure higher probability of population persistence (Hastings & Botsford, 2006a; Artzy-Randrup & Stone, 2010), higher metapopulation growth rates (Hanski & Ovaskainen, 2000), higher resilience to disturbances (Blowes &

Figure 3 Connections between MPAs for 1970–1999 (a) and 2070–2099 (b). Colours represent the probability of connections.

Connolly, 2012). Increased connectance can also increase gene flow and the spread of genetic variants conferring adaptation to novel environmental conditions. This is relevant in the context of adaptation to climate change itself, where warm-tolerant populations from the Southern Mediterranean may contribute adaptive alleles to Northern less tolerant populations (Bodilis *et al.*, 2003). Examination of connectivity patterns among MPAs can inform the design and placement of new PAs to favour spread of adaptive alleles in order to increase resistance to climate change (Mumby *et al.*, 2011).

The two other metrics of connectivity (extent of the continental shelf seeded by MPAs and the concentration of larvae in the seeded areas) are especially important for exploited species and are directly related to the ability of MPAs to provide benefits to exploited areas in the form of adult spillover and larval supply (Gaines *et al.*, 2010). Larval export from MPAs to fished areas can provide recruitment supply and the magnitude of the benefits depends largely on the larval dispersal capacity and the level of exploitation inside and outside MPAs (Kaplan *et al.*, 2009). Larger benefits are possible for well-enforced MPAs that provide effective protection from fishing and higher productivity compared with exploited areas, and for species with short dispersal distances (Pelc *et al.* 2010). The decrease in seeded area and the increase in larval retention fraction predicted in our simulations would produce higher concentration of larvae on progressively smaller zones of the continental shelf. The increase in larval concentration, combined with the predicted decrease in larval dispersal distances, can supply exploited areas with higher densities of larvae. However, the benefits of higher larvae densities are counterbalanced by a reduction in seeded area. This would lead to higher benefits for fished areas surrounding MPAs but lower benefits for fished areas that are located too far from MPAs, leading to geographical disparities in the benefits of MPAs for fisheries.

Different mechanisms affecting connectivity under climate change

The four metrics of connectivity will be affected by climate change through different mechanisms (i.e. hydrodynamics, adult reproductive timing and larval growth rates). We found that changes in hydrodynamics have small effects relative to the two other biological mechanisms. While some studies have evidenced how changes in hydrodynamic driving factors such as wind, temperatures and river discharges can affect connectivity (Ayata *et al.*, 2010; Huret *et al.*, 2010; Brochier *et al.*, 2013), our study shows that hydrodynamic changes over the current century would slightly reduce larval dispersal distances, extent of seeded area and larval retention fraction and would have no effect on connectance.

Adult reproductive timing would have an appreciable effect only on connectance. Adult reproductive timing controls the number of reproductive events per MPA and their temporal distribution. Both the number and the temporal

distribution of reproductive events can affect connectivity. In our case, the largest effect seems due to the number of reproductive events. Indeed, our model was based on the dusky grouper, a species whose reproduction is limited by low temperatures. As a consequence, reproductive events (and then larval releases) were not possible in MPAs located in too cold places. Therefore, an increased number of MPAs did not contribute larvae in the first years of the 1970–2099 study period (Fig. S3 in Supporting Information). This decreased connectance in the first years and produced the increasing trend in connectance as more and more MPAs became suitable for reproduction. Conversely, for species limited by high temperature, a reduction in the number of MPAs suitable for reproduction with time and therefore a reduction in connectance is expected. In the Mediterranean, climate warming (high temperatures) limits not only the reproductive potential but also the geographic distribution of some species. Among endemic species, 59% are predicted to restrict their geographic range over the current century and most of them will also experience high fragmentation (Lasram *et al.*, 2010). For such species, the current system of MPAs will likely lose connectance.

The temporal distribution of reproductive events did not have an appreciable effect on connectivity. Seasonal variation in hydrodynamics shapes the distribution of marine organisms and will affect connectivity patterns if the timing of larval releases is shifted earlier (Ayata *et al.*, 2010). Climate change can cause earlier releases of larvae through temperature increase when adult reproductive biology respond positively to temperature (Lett *et al.*, 2010). In addition, such a physiological response would manifest itself immediately following temperature increase, while temperature-driven changes in current speed and direction would be slower due to the much greater inertia of hydrodynamics. It was therefore expected to see changes in connectivity due to temporal shift in adult reproductive timing. However, in our system, the increased suitability of MPAs to adult reproduction seems more important to explain connectance than the shift in reproductive timing from late to early summer. Possibly, the effects of temporal reproductive shifts can become apparent at smaller spatial scales, while they remain masked at the scale of the whole system of MPAs.

The temperature-driven changes in larval growth rates strongly influence the connectivity pattern through time. As a result of faster larval growth rates, we observed a reduction in dispersal distances, connectance and seeded area and an increase in larval retention. The climatic conditions of the Mediterranean basin are expected to change over the current century, with a SST increase in [0.8; 1.8] °C for the 2021–2050 period with respect to 1961–1990 on average over the entire basin [A1B scenario, (Gualdi *et al.*, 2012)] and an expected increase of 2.8 °C in the current simulation. As expected, higher temperatures lead to faster metabolic rates and therefore a shorter pre-competency phase for larvae, which reach settlement length faster (O'Connor *et al.*, 2007). However, the increase in metabolic activity will increase

growth rates only if larvae find enough food and is dependent on the availability and abundance of plankton. The distribution of plankton is expected to become more variable with climate change and may thus reduce effective larval growth rates and even lead to increased larval death rates through starvation (Munday *et al.*, 2009a).

Our statistical analyses did not reveal any significant interaction between changes in adult reproductive timing and larval growth rates. An interaction may be possible if earlier reproduction may expose larvae to different water temperatures through change in dispersal routes, and there is no need to expect that the effect on connectivity will be additive. The absence of an interaction does not mean that the effects of different processes on connectivity can be studied separately, because the simple additivity of the effects can change the predictions not only quantitatively but also qualitatively. For example, disregarding the effects of adult reproductive timing on connectance would erroneously lead to predict that connectance will decrease as a result of increased larval growth rates, while including the adult effects lead us to the conclusion of an increase in connectance.

Several other processes can affect connectivity and are themselves affected by environmental conditions and climate change. These processes can alter connectivity during the emigration, dispersal and immigration phase (Travis *et al.*, 2013). Most important for marine fish are larval mortality, larval behaviour, reproductive output, swimming ability and orientation ability (Cowen *et al.*, 2006; Leis, 2007; Munday *et al.*, 2009a; Ayata *et al.*, 2010; Treml *et al.*, 2012). In particular, reproductive output may be subject to temperature control and thus play in the same manner as the effect we observe on reproductive timing, reinforcing connectance due to increased larval releases. Larval mortality rates may be increased by extreme lethal temperatures or by the increased variability of nutrient supply expected under climate change (Munday *et al.*, 2009a). On the other hand, the shorter duration of larval transport and pre-competency period due to faster metabolic rates may reduce the overall planktonic mortality. While the processes affecting connectivity are numerous and likely have important implications, this is the first time, to our knowledge, that two of these processes (namely adult reproduction and larval growth) are modelled jointly to derive the effects of climate change on connectivity.

Model limitations and assumptions

Predicting the impact of climate change on larval connectivity is a challenging task because of uncertainties intrinsic to model parameter estimation and collected data: (1) a first source of uncertainty is related to multiple emission scenarios depending on future socio-economic and political choices (IPCC *et al.*, 2001); here, we have used only one scenario to force the atmospheric model, but it remains the only available for the Mediterranean. (2) For a given scenario, there are uncertainties concerning Mediterranean Sea forcings, that

is, the atmospheric variables, the near-Atlantic ocean characteristics and the river runoff fluxes; these forcings are used to drive the hydrodynamic model. (3) For a given scenario and a given set of forcings, a third source of uncertainty is the choice of regional ocean model itself; in particular, its physical parameterizations and its horizontal and vertical resolutions are key elements of the model design when trying to reproduce coastal circulation in some areas (such as bays and estuaries) (Largier, 2003; Siegel *et al.*, 2003; Werner *et al.*, 2007). (4) We used the best available knowledge on larval biology for the chosen species (Glamuzina *et al.*, 1998; Spedicato & Boglione, 2000; Cunha *et al.*, 2009) but growth rates and behaviour in the wild (Macpherson & Raventos, 2006) will likely differ from the results of laboratory studies; moreover, no data are available on important parameters such as salinity, nutrient availability and natural mortality rates. (5). There is also limited knowledge on adult biology, including species distribution and abundance (Zabala *et al.*, 1997; Lembo *et al.*, 1999; Bodilis *et al.*, 2003; Renones *et al.*, 2007, 2010), and spawning behaviour may differ from the observations used in our work, which were collected in a single study site in North-Western Mediterranean (Hereu *et al.*, 2006). The effect of these uncertainties is discussed in Appendix S2 in Supporting Information.

Implications for conservation and management

Connectivity is an important criterion for the design and implementation of new PAs (Crooks & Sanjayan, 2006; Moilanen *et al.*, 2009). In addition to enhancing species persistence and biodiversity representation, in the case of exploited species, connectivity from PAs to unprotected areas can offer benefit for harvesting and economic human activities (Gaines *et al.*, 2010; Tolon *et al.*, 2012). According to the Strategic Plan for Biodiversity adopted by the Convention on Biological Diversity (COP10; www.cbd.int/cop10), protected areas are targeted to cover 10% of the marine surface and 17% of terrestrial habitats by 2020 and must form well-connected networks.

In the Mediterranean Sea, this means increasing the geographic extent of MPAs by one order of magnitude, from the actual 1% (excluding the Pelagos Sanctuary; www.med-pan.org/med_mpa_analysis) to the targeted 10%. It is therefore important that new MPAs be created following a systematic strategy for conservation at the scale of the entire Mediterranean basin (Giakoumi *et al.*, 2012; Micheli *et al.*, 2013). The criteria for choosing sites for protection should be based on maximizing the representation of biodiversity (Coll *et al.*, 2010), including phylogenetic and functional diversity (Mouillot *et al.*, 2011) and minimizing the anthropogenic pressures that jeopardize biodiversity (Coll *et al.*, 2012). In addition to representing adequately and comprehensively the spatial distribution of present biodiversity, conservation planning should also aim at protecting the processes that will maintain diversity in the future (Pressey *et al.*, 2007; Almany *et al.*, 2009). Connectivity is one of

these processes as it is essential to ensure population stability and persistence (Armsworth, 2002; Hastings & Botsford, 2006b) and justifies the need for further research aimed at better characterizing current patterns of connectivity and predicting their future evolution (Mumby *et al.*, 2011; Lemes & Loyola, 2013).

To reach a realistic integration of connectivity on conservation planning within a climate change context, we need to consider multiple effects combining several species traits potentially modified under temperature increase and to determine whether such effects are additive, compensating or synergistic on connectivity patterns.
